

## 3. CIF DATA DEFINITION AND CLASSIFICATION

`_pd_meas_rocking_angle` is used to record the angular range through which the sample is rocked, where 360 indicates that one complete revolution occurs during each counting period. Numbers greater than 360 are possible.

**3.3.8.9. Use of an incident-intensity monitor**

For radiation sources for which the intensity may vary, such as synchrotron-radiation sources, the intensity of the incident radiation is measured using an incident-intensity monitor. This value may be specified for every data point using `_pd_meas_counts_monitor` (or `_pd_meas_intensity_monitor`) by including this data item in the loop with the diffraction intensities. For some instruments, counting times are set so that the same number of monitor counts are measured for each data point. If this is the case, `_pd_meas_counts_monitor` will be the same for every data point and need not be included in the loop.

**3.3.8.10. Recording detector livetime**

The detector deadtime is often more a function of the counting electronics than of the intrinsic properties of the detector. In these circumstances, the counting circuit may provide a gating signal that indicates when the electronics are processing an event *versus* when the circuit is idle and waiting for an event to process. From this gating signal, a detector livetime signal can be generated. Livetime is a better way to correct intensities than applying a deadtime correction, because if appreciable numbers of events are processed but are not counted (for example, counts due to fluorescence), the actual deadtime can be quite high, even though the recorded number of counts can be quite low. To use the livetime signal, the count time can be multiplied by the livetime or the livetime can be treated as a monitor (see Section 3.3.8.9). If an incident-intensity monitor and a livetime are both available, the `_pd_meas_intensity_monitor` value can contain the incident intensity times the livetime.

**3.3.9. Use of pdCIF for Rietveld refinement results**

One of the major aims of the development of the pdCIF definitions was to be able to communicate the results of Rietveld refinements, and this is expected to be the most common use for pdCIF. To aid the development of software that prepares pdCIF output from Rietveld refinements, this section describes the blocks and loops to be found in a pdCIF, noting variations due to the type of Rietveld refinement. Programmers may also wish to look at the *GSAS2CIF* program, which creates CIFs for a wide range of types of diffraction data, and for multiple data sets and phases (Toby *et al.*, 2003).

It is valuable for the CIF to contain the structural model(s), the observed powder-diffraction intensities and the calculated powder-diffraction intensities so that the fit of the model to the observed diffraction pattern can be viewed graphically. It is the present author's firm belief that it is impossible to judge the quality of a Rietveld refinement by *R* factors or any other numerical metric, since these values describe not just how well the structural model fits the measurements, but also how well the background and peak shape are fitted as well. Very poor models can have good *R* factors and  $\chi^2$  values if there is a significant amount of non-Bragg scattering that has been well fitted. On the other hand, with high-resolution observations measured to excellent precision, even trivial imperfections in the peak shapes can result in poor agreement factors. There is no substitute for the visual examination of a plot of the observed and calculated patterns, optimally at more than one magnification level. The program *pdCIFplot* (Toby, 2003) plots the observed and calculated powder-diffraction intensities in a pdCIF

and allows the fit to be examined in more detail than can be provided by a figure showing the whole profile at once.

**3.3.9.1. A single phase**

When a single set of diffraction measurements is used to model a single phase, a pdCIF will usually contain only one block. There will be several important loops present.

One loop will contain atomic parameters, such as coordinates. The unit cell must also be specified.

A second loop will contain the reflection table.

A third loop will contain the observed (or processed) diffraction measurements and the simulated pattern. Other items that should be included in this loop are the least-squares weights (usually  $\sigma^{-2}$ , where  $\sigma$  is the standard uncertainty) so that it is possible to determine the quality of the fit in individual regions. Weight values of zero can also be used to indicate that data points have been excluded from the refinement. Since background fitting is quite important in Rietveld analysis, it is also valuable to include the background values. Thus, this loop should specify:

(i) the ordinate of the Rietveld plot, using one or more of: `_pd_meas_2theta_scan`, `_pd_meas_time_of_flight`, `_pd_proc_2theta_corrected`, `_pd_proc_d_spacing` or `_pd_proc_recip_len_Q`; alternatively the ordinate can be specified using either `_pd_meas_2theta_range_*` or `_pd_proc_2theta_range_*`, where `_*` is `_min`, `_max` and `_inc` outside the loop.

It is recommended that all CIFs describing the results of a Rietveld refinement include either `_pd_proc_d_spacing` or `_pd_proc_recip_len_Q`.

(ii) The observed (or processed) intensity values, using the items `_pd_meas_counts_total`, `_pd_meas_intensity_total`, `_pd_proc_intensity_total` or `_pd_proc_intensity_net`.

(iii) The background, using the item `_pd_proc_intensity_bkg_calc`.

(iv) The least-squares weights, using the item `_pd_proc_ls_weight`. If these weights are not specified, then it must be presumed that all points have been used in the refinement and that the weights are the reciprocal of the intensity values (if `_pd_meas_counts_total` was used) or the reciprocal of the intensity standard uncertainties, if specified.

(v) The calculated pattern should appear using either `_pd_calc_intensity_net` or `_pd_calc_intensity_total`.

It is good practice always to include at least one data item from each entry in the list above.

Apart from the information contained in these loops, information from almost all sections of the pdCIF dictionary can be valuable. Such items include data items that define how the diffraction measurements were made, how the sample was prepared and characterized, how the refinement was performed, and least-squares parameters and *R* factors. A template and an example pdCIF showing the combined use of pdCIF and core data items form part of the *Acta Crystallographica* instructions for authors at <http://journals.iucr.org/services/cif/powder.html>.

**3.3.9.2. Multiple phases**

When more than one phase is present, multiple CIF blocks are needed. The resulting CIF will contain much the same information as would be found in a single-phase pdCIF, as described in Section 3.3.9.1. However, there will be a separate block for each phase containing information specific to that phase, such as the unit cell and the loop containing the atomic parameters.

The CIF will usually (see Section 3.3.7) contain one additional block with the observed and calculated pattern and a reflection table, as well as the other data items that define how the
