5.5. The use of mmCIF architecture for PDB data management

BY J. D. WESTBROOK, H. YANG, Z. FENG AND H. M. BERMAN

5.5.1. Introduction

The Protein Data Bank (PDB) is an archive for macromolecular structures (Bernstein et al., 1977; Berman et al., 2000) and a major component of a global resource for macromolecular structural science (Berman et al., 2003). The scale of its data handling operations is large, and depends on the effective exploitation of the latest developments in the science and technology of informatics. A significant component of its data storage and retrieval strategy is the management of structural data in mmCIF format with appropriate extensions.

Over its 30-year history, the PDB archive has grown from seven entries in 1973 to a collection of over 30,000 structures as of May 2005. The growth in the size of the archive has been accompanied by increases in both data content and in the structural complexity of individual entries. As the PDB has grown, there has been a significant broadening of its user community. In response to this change, the role of the PDB has expanded from being simply a provider of structure data files to providing a key information resource for the structural biology community.

Looking forward, an acceleration in the growth of the PDB archive is anticipated owing to developments in high-throughput structural determination methodologies and worldwide structural genomics efforts. To support the continued growth and evolution of the PDB archive, a framework is required that supports automation and scalability, and that can adapt to changes in both data content and delivery technology.

At the core of the PDB informatics infrastructure is an ontology of data definitions which electronically encode domain information in the form of precise definitions, examples and controlled vocabularies. In addition to domain information, data definitions also encode information such as data type, data relationships, range restrictions and presentation units.

The software-accessible PDB exchange data dictionary (Appendix 3.6.2) is the key part of the PDB informatics infrastructure. The exchange dictionary is an extension of the macromolecular Crystallographic Information File (mmCIF) data dictionary (Bourne et al., 1997). The dictionary provides the foundation for software tools which exchange and validate data, create and load databases, translate data formats, and serve application program interfaces. The components of the informatics infrastructure developed by the PDB are being used to build a data pipeline to support high-throughput structure determination.

5.5.2. Representing macromolecular structure data

Macromolecular structure data have historically been represented in a simple record-oriented format developed by the PDB; this format has been widely used in structural and computational biology.

developed for other types of diffraction experiments, electron-microscopy data and for the general description of image data. The metadata concepts and tools that have been developed to support mmCIF are sufficiently general that they may be applied to the description of data in virtually any application.

The demands of structural genomics projects have driven the development of extensions to capture an increased level of experimental detail. These are available at http://mmcif.pdb.org/. Extensions have also been introduced to describe NMR, cryo-electron microscopy and all aspects of protein production. The ability to rapidly add extensions and incorporate these into the PDB data-processing system is an important feature for supporting the rapidly evolving technologies associated with high-throughput structure determinations.

The mmCIF metadata architecture is built from three levels as illustrated in Fig. 5.5.2.2 (see also Chapter 2.6). Individual data files are described at the top level (e.g. Fig. 5.5.2.2a). The contents of these data files are defined by a data dictionary (e.g. Fig. 5.5.2.2b) in the next lower level (see Chapters 3.6 and 4.5). The attributes used in this data dictionary to build data definitions are in turn defined in the dictionary description language (DDL) (e.g. Fig. 5.5.2.2c) in the lowest level (see Chapters 2.6 and 4.10).

The major syntactical constructs used by mmCIF are illustrated in the data file example of Fig. 5.5.2.2(a). Each data item or group of data items is preceded by an identifying keyword. Groups of related data items are organized into data categories. Two categories, CELL and ENTITY_POLY_SEQ, are shown in the example. CELL contains an individual instance describing a single set of crystallographic cell constants. ENTITY_POLY_SEQ contains a loop. These syntactic constructs are used to describe a polymer residue sequence. Essentially all mmCIF data are described as a set of tabular data structures.

Each mmCIF data item is defined in a data dictionary. Data definitions are given between save-frame delimiters (i.e. save_); apart from this, the data definitions share the same simple syntax as used in data files. An example definition for a crystallographic cell constant is shown in Fig. 5.5.2.2(b). Many features of the cell constant are described in this definition, including data type, range restrictions, units of expression, dependent quantities, related definitions, necessity and related precision estimate. Although not shown in this example, dictionary definitions can also include parent-child relationships that have important consequences in maintaining data consistency.

The attributes of each data definition are defined in the DDL dictionary. Fig. 5.5.2.2(c) shows example DDL definitions describing data types. DDL definitions have the same syntax as definitions used in the data dictionary. Because the attributes of the DDL are also used in DDL definitions, this metadata architecture is described as self-defining.

The RCSB PDB distributes parsing tools that support all three levels of this metadata architecture (http://sw-tools.pdb.org/). The CIFPARSE_OBJ package (Tosic & Westbrook, 2000) provides high-level methods to read, write, validate and manage data from data files, dictionaries and DDLs. Data files can be validated relative to an input data dictionary, and dictionary files can be validated relative to an input DDL. CIFPARSE_OBJ stores information in a collection of table objects. Access methods are provided to search and manipulate the table objects. A companion package, CIFOBJ (Schirripa & Westbrook, 1996), provides an alternative representation of dictionary and DDL data. CIFOBJ organizes dictionary information into a collection of category and item-level objects. Access methods are provided for all dictionary attributes.
5.5.2.3. Supporting other data formats and data delivery methods

One of the greatest benefits of a dictionary-based informatics infrastructure is the flexibility that it provides in supporting alternative data formats and delivery methods. Because the data and all of their defining attributes are electronically encoded, translation between data and dictionary formats can be achieved using lightweight software filters without loss of any information.

XML provides a particularly good example of the ease with which data can be converted to and from the mmCIF format. XML translations of mmCIF data files are currently provided on the Worldwide PDB ftp site (ftp://ftp.wwpdb.org/pub/pdb/data/structures/divided/XML/). These XML files use mmCIF dictionary data-item names as XML tags. These files were created by a translation tool (http://sw-tools.pdb.org/apps/MMCIF-XML-UTIL/) that translates mmCIF data files to XML in compliance with an XML schema. The XML schema is similarly software-translated from the PDB exchange data dictionary.

Other delivery methods such as Corba (http://www.omg.org/cgi-bin/doc?lifesci/00-02-02) do not require a data format, as data are exchanged using an application program interface (API). A Corba API for macromolecular structure (Greer et al., 2002) based on the content of the mmCIF data dictionary has been approved by the Object Management Group (OMG). Software tools supporting this Corba API (OpenMMS, http://openmms.sdsc.edu, and FILM, http://sw-tools.pdb.org/apps/FILM) take full advantage of the data dictionary in building the interface definitions and supporting server on which the API is based (see also Section 5.3.8.2).

5.5.3. Integrated data-processing system: overview

The RCSB PDB data-processing system has been designed to take full advantage of the features of the mmCIF metadata framework. The AutoDep Input Tool (ADIT) is an integrated data-processing system developed to support deposition, data processing and annotation of three-dimensional macromolecular structure data.

This system, which is outlined in Fig. 5.5.3.1, accepts experimental and structural data from a user for deposition. Data are input in the form of data files or through a web-based form interface. The input data can be validated in a very basic sense for syntax compliance and internal consistency. Other computational validation can also be applied, including checking the input structure data against a variety of community standard geometrical criteria and comparing the input experimental data with the derived structure model. The suite of validation software used within ADIT is distributed separately (http://sw-tools.pdb.org/apps/VAL/). All of this validation information is returned to the user as a collection of HTML reports.

In addition to providing data-validation reports, ADIT also encodes data in archival data files and loads data into a relational database. The loading of data into the relational database is aided by an expert annotator. The ADIT system customizes its behaviour according to the user’s requirements. One important distinction is between the behaviour of the interface provided for depositing data and that of the interface used for annotating the data. The depositor is focused only on data collection and provides the simplest possible presentation of the information to be input. The annotator sees the detail of all possible data items as well as the full functionality of the supporting data-processing software and database system.

Although the ADIT system was originally developed to support the centralized data deposition and annotation of macromolecular structure data, it is not limited to these particular applications. Because the architecture of the ADIT system derives the full scope of information to be processed from a data dictionary, the system can transparently provide data input and processing functionality for any content domain. This feature has been exploited in building a data-input tool for the BioSync project (Kuller et al., 2002). The ADIT system can also be configured in workstation mode to provide single-user data collection and processing functionality. This version of the ADIT system as well as the supporting mmCIF parsing and data-management tools are currently distributed by the RCSB PDB under an open-source licence (http://sw-tools.pdb.org/apps/ADIT).

5.5.3.1. ADIT: functional description

The basic functions of the ADIT deposition system are shown in Fig. 5.5.3.2. Users interact with the ADIT system through a web server. The CGI components of the ADIT system (that is, functional software components interacting with web input data through the Common Gateway Interface protocol) dynamically build the HTML that provides the system user interface. These CGI components are currently implemented as compiled binaries from C++ source code.

User data can be provided in the form of data files or as keyboard input. Input files can be accepted in a variety of formats. ADIT uses a collection of format filters to convert input data to the data specification defined in a persistent data dictionary. Data in the form of data files are typically loaded first. Any input data that are not included in uploaded files can be keyed in by the user. ADIT builds a set of HTML forms for each category of data to be input. At any point during an input session, a user may choose to view or deposit the input data. Users who are depositing data may also use the data-validation services through the ADIT interface.

Comprehensive data ontologies like the PDB exchange dictionary contain vast numbers of data definitions. A data-input application may only need to access a small fraction of these definitions at any point. To address the problem of selecting only the relevant set of input data items from a data dictionary ADIT uses a view database. In addition to defining the scope of the data items to be edited by the ADIT application, an ADIT data view also stores
